Notebook 5: Advanced XAI Analysis

This notebook marks the transition from basic model interpretability (identifying key features) to advanced explainable artificial intelligence (XAI), focusing on the practical and ethical applications of the best-performing baseline models: Tuned Logistic Regression and Tuned XGBoost. We employ SHAP and LIME not merely to list important features, but to rigorously test the stability, fairness, and temporal relevance of the model's predictive insights.

XGBoost SHAP: Temporal Explainability

This procedure fully implements the Temporal Explainability objective (Section 3.4.1) by applying SHAP to the XGBoost Classifier across the course's duration. The process begins by creating a unique temporal dataset where feature values (VLE clicks, assessment scores) are cumulatively aggregated for each of the 26 weeks, capturing the evolution of student engagement over time. After training the final XGBoost model on this dynamic dataset, the core analysis involves an iterative loop: in each of the 26 weekly cycles, SHAP values are calculated only for the data points corresponding to that specific week. This technique allows us to pinpoint the exact moment when a feature's predictive influence changes (e.g., when early demographic factors give way to mid-course engagement metrics like the number of submitted assessments). The mean absolute SHAP values for each week are then compiled into the temporal_shap_importance DataFrame, providing the quantitative evidence needed to plot and analyze the trajectory of feature importance throughout the course, which is essential for identifying the optimal intervention time.

XGBoost LIME: Temporal Explainability

This procedure implements the Temporal Explainability objective (Section 3.4.1) using LIME with the XGBoost Classifier, providing an instance-specific, model-agnostic perspective on the feature importance trajectory. The goal is to see how the locally important factors change as the course progresses, complementing the global view offered by SHAP.

The process utilizes the pre-trained XGBoost model and the same weekly aggregated temporal test set. LIME is initialized once using the structure of the training data. Then, a loop iterates through each of the 26 weeks. Within each week, LIME explanations are generated for a small sample of students (up to 50), which is a necessary step since LIME is computationally slow. For each sampled student, LIME creates a local, linear proxy model to explain the complex XGBoost prediction, resulting in a list of weighted feature contributions.

Logistic Regression SHAP: Temporal Explainability

This procedure implements the Temporal Explainability by applying SHAP to the linear Logistic Regression model, tracking the evolution of its feature reliance over the course's 26 weeks. The approach leverages the same weekly aggregated temporal test set created previously.

The process begins by initializing the specialized shap.LinearExplainer, which is highly efficient for the linear structure of the Logistic Regression model, using the training data as its baseline. A loop then iterates through each of the 26 weeks in the test set. In each weekly step, the SHAP values are calculated only for that week's data points. This is key because although the model's coefficients (the underlying weights) are static, the impact of cumulative features (like total clicks and submissions) changes as their numerical values increase each week.

For every week, the mean absolute SHAP value for all features is calculated, quantifying the average predictive influence of that feature at that point in time. These weekly importance scores are compiled into the temporal_shap_importance DataFrame, which is then used to plot the trajectory of the top features over time. This analysis is crucial as it verifies whether the linear model's interpretation of causality aligns with the course timeline, identifying the key weeks where features like student engagement begin to exert the strongest, most stable linear pull on the dropout prediction.

Logistic Regression LIME: Temporal Explainability

This procedure implements the Temporal Explainability using LIME with the linear Logistic Regression model, tracing the evolution of locally important features over the course's 26 weeks. The method is used to provide an instance-specific, human-readable view of which features are driving predictions at different points in time.

The process starts by initializing the LimeTabularExplainer once on the training data. Then, a loop iterates through each of the 26 weeks in the temporal test set. Due to LIME's computational cost, explanations are generated for a sample of up to 50 students each week. For every sampled student, LIME creates a simple, local linear model to interpret the complex model's prediction, yielding a set of weighted feature contributions (the raw LIME explanation).

To create a temporal trend, the absolute values of these local LIME contributions are aggregated and averaged across all sampled students within that week. This calculated Mean Absolute LIME Importance for each feature is stored, building the temporal_lime_importance DataFrame. This final DataFrame allows for the visualization of how the most locally persuasive features change week-to-week, providing a complementary perspective to the SHAP analysis by illustrating the shifting immediate rationale behind the linear model's sequential predictions.

XGBoost LIME: Fairness & Bias Auditing

This procedure directly implements the Fairness & Bias Auditing objective using LIME with the complex XGBoost Classifier to rigorously determine if the model exhibits disparate treatment across demographic subgroups. The analysis systematically selects key features, such as gender, age_band_35_55, and disability_Y, and iterates through each category within those features to define distinct student subgroups. For every subgroup, a sample of students from the test set is taken, and a LIME explanation is generated for each one, providing the local linear rationale behind the complex XGBoost prediction. To audit for bias, the absolute values of these local LIME feature contributions are then aggregated and averaged across all sampled students within that specific group. The final output is a comparative table of the Top 10 most influential features for each subgroup, which allows us to quantitatively assess if the model is relying on ethically sensitive characteristics (like demographics) for one group more than another, a finding that is crucial for validating the model's ethical robustness.

Logistic Regression SHAP: Fairness & Bias Auditing

This procedure directly implements the Fairness & Bias Auditing objective using SHAP with the Logistic Regression model, comparing the model's feature reliance across key demographic segments. The goal is to see if the model's transparent, linear reasoning changes significantly based on sensitive features.

The analysis utilizes the shap.LinearExplainer and systematically iterates through all categories within selected demographic features: gender, age_band_35_55, and disability_Y. For each resulting subgroup (e.g., students with disability_Y == 1), the test data is filtered, and SHAP values are calculated specifically for those instances. This calculation quantifies the exact contribution of every feature to the prediction for students within that group.

The final step involves two crucial analyses for each subgroup:

Global Visualization: A SHAP summary plot is generated, visually displaying the overall feature importance (mean absolute SHAP) for that specific subgroup.

Quantitative Auditing: The Top 10 most impactful features are extracted from the mean absolute SHAP values.

By comparing the feature importance rankings and magnitudes across contrasting groups (e.g., comparing students in the '35-55' age band with those outside it), we can audit the Logistic Regression model. A disparity in the non-demographic features that drive the prediction for different groups indicates disparate impact (i.e., different feature sets lead to similar outcomes), whereas a reliance on the demographic feature itself for one group might indicate algorithmic bias. This process establishes the ethical baseline for the simpler model.

Logistic Regression LIME: Fairness & Bias Auditing

This procedure directly implements the Fairness & Bias Auditing by applying LIME to the linear Logistic Regression model, comparing the model's localized feature reasoning across specific demographic groups. The audit aims to identify if the model's linear decision-making process is consistent and fair, or if it relies on different feature sets to predict outcomes for different students.

The analysis is performed by first initializing the LimeTabularExplainer on the training data. It then systematically iterates through distinct student subgroups defined by the selected demographic features: gender_M, age_band_35_55, and disability_Y. For each subgroup, a random sample (up to 50 students) is extracted from the test set. For every sampled student, a LIME explanation is generated, which creates a local, simple model to explain the Logistic Regression prediction for that individual.

To conduct the audit, the mean absolute LIME feature contributions are aggregated and averaged across all sampled students within each subgroup. The final output is a comparative table detailing the Top 10 most influential features for each group. By contrasting these ranked feature lists across groups (e.g., comparing the important features for students with a disability vs. those without), we can determine if the model's linear reliance shifts, allowing us to assess the ethical consistency of the baseline model's predictions.

```

XGBoost SHAP: Explanation Robustness

This procedure details the implementation of Explanation Robustness using SHAP on the complex XGBoost Classifier to confirm the stability and trustworthiness of its feature explanations. The analysis focuses on a single instance (Student Index 50) and compares its initial SHAP explanation against a perturbed explanation. First, the original SHAP values are calculated for the student, establishing the baseline feature contributions and the model's prediction. Second, a small, controlled 5% increase (the perturbation) is applied to a highly influential feature, total_clicks, simulating a minor, realistic change in student behavior, and a new prediction is generated. Finally, new SHAP values are calculated for this perturbed instance. Robustness is qualitatively determined by comparing the Top 5 features and the magnitudes of their SHAP values across the original and perturbed explanations. If the feature ranking and magnitude remain largely stable despite the small input change, the explanation is deemed reliable and suitable for high-stakes decision-making, providing key evidence on the practical trustworthiness of the model's reasoning.

XGBoost LIME: Explanation Robustness

This procedure details the implementation of Explanation Robustness using LIME on the XGBoost Classifier, assessing the stability of its local explanations against minor input changes. The goal is to ensure that a small change in a student's data doesn't lead to a wildly different local explanation, confirming the trustworthiness of LIME's rationale.

The analysis is performed on a single student (Index 50) and follows a three-part comparative process:

Original Explanation Baseline: The LimeTabularExplainer is initialized on the training data. The original LIME explanation is generated for the student instance, providing the Top 5 features and their numerical contribution (the local model's coefficient) to the original XGBoost prediction.

Controlled Perturbation: A minor, controlled change—specifically, a 5% increase in the critical feature total_clicks—is applied to the student's data. A new prediction is then generated for this perturbed instance.

Stability Comparison: A new LIME explanation is calculated for the perturbed student. The robustness is then assessed by comparing the Top 5 features' rankings and the magnitude of their contributions between the original and perturbed LIME explanations. A robust explanation will show minimal changes in feature ranking and contribution, validating LIME's reliability as a local fidelity tool for the complex XGBoost model. This evidence is vital for arguing the practical utility of the model's insights.

Logistic Regression SHAP: Explanation Robustness

This procedure details the implementation of Explanation Robustness using SHAP on the Logistic Regression model, which is essential to confirm the stability of the linear model's explanations. This test verifies that the model's transparent reasoning isn't easily manipulated by minor input changes. The analysis focuses on a single instance (Student Index 50) and follows a three-part comparative process: First, the original SHAP values are calculated using the specialized shap.LinearExplainer, establishing the baseline ranking and magnitude of the top feature contributions. Second, a small, targeted perturbation—specifically, a 5% increase in the influential feature total_clicks—is applied to the student's data, and a new prediction is generated. Finally, new SHAP values are calculated for the perturbed instance. Robustness is then assessed by comparing the Top 5 features' rankings and the magnitude of their SHAP values between the original and perturbed explanations. Since Logistic Regression is inherently linear, the feature rankings should remain highly stable, confirming the model's predictable and reliable behavior under this critical

Logistic Regression LIME: Explanation Robustness

This procedure details the implementation of Explanation Robustness using LIME on the Logistic Regression model, which is necessary to assess the stability of LIME's local explanations for the linear baseline. The analysis focuses on a single instance (Student Index 50) and follows a three-part comparative process: First, the original LIME explanation is generated for the selected student, establishing the baseline features and their contributions to the original Logistic Regression prediction. Second, a minor, targeted perturbation—specifically, a 5% increase in the influential feature total_clicks—is applied to the student's data, and a new prediction is generated. Finally, a new LIME explanation is calculated for the perturbed instance. Robustness is assessed by comparing the Top 5 features' rankings and the magnitude of their contributions between the original and perturbed explanations. Since the underlying model is linear, the LIME

```

XGBoost SHAP: Explanation Clustering

This procedure details the implementation of Explanation Clustering using SHAP and the XGBoost Classifier. This advanced technique moves beyond general feature importance to identify distinct student personas or subgroups based on the reasons why the model predicts their outcome, enabling highly targeted intervention strategies.

The methodology begins by calculating the SHAP values for the entire test set using the shap.TreeExplainer. These SHAP values, which quantify each feature's contribution to every student's prediction, form a new feature space for clustering. K-Means clustering is then applied directly to this matrix of SHAP values to group students who share a similar underlying risk profile, irrespective of their final prediction. For this analysis, three distinct clusters (n_clusters=3) are created, each representing a unique "reason for risk."

To characterize these newly formed Explanation Clusters, the mean absolute SHAP value for every feature is calculated within each cluster. This provides a clear quantitative breakdown of the features that are most predictive for that specific student persona. The final step involves suggesting policy interventions tailored to the top feature driving each cluster's risk (e.g., policy focuses on assessment support if submission count is the top feature). This entire process transforms model output into actionable educational profiles for the dissertation's policy recommendations.

```
